**Abstract**— We propose some improvements of TCP Vegas and compare its performance characteristics with TCP Reno. We argue through analysis that TCP Vegas, with its better bandwidth estimation scheme, uses the network resources more efficiently and fairly than TCP Reno. Simulation results are given that support the results of the analysis.

**Keywords**—TCP Reno, TCP Vegas, Congestion Control, Fairness

## I. INTRODUCTION

Following a series of congestion collapses starting in October of '86, Jacobson and Karels developed a congestion control mechanism, which was later named TCP Tahoe [9]. Since then, many modifications have been made to the transmission control protocol (TCP) and several different versions of TCP have been implemented [9], [10].

Recently Brakmo *et al.*[2] have proposed a new version of TCP, which is named TCP Vegas, with a fundamentally different congestion avoidance scheme from that of TCP Reno (4.3BSD) and claimed that TCP Vegas achieves 37 to 71 percent higher throughput than TCP Reno. Ahn *et al.*[1] have evaluated the performance of TCP Vegas on their wide area emulator and shown that TCP Vegas does achieve higher efficiency than TCP Reno and causes much fewer packet retransmissions. However, they have observed that TCP Vegas, when competing with other TCP Reno connections, does not receive a fair share of bandwidth.

Floyd has observed that TCP Reno is biased against the connections with longer delays [5], [7]. The intuition behind this behavior is as follows. While a source does not detect any congestion, it continues to increase its window size by one during one round trip time. Obviously connections with a shorter delay can update their window sizes faster than those with longer delays, and thus capture higher bandwidths. Based on this observation, Floyd and Jacobson [6] have proposed a *constant rate adjustment* algorithm. Henderson *et al.*[8] have simulated a variation of this scheme and reported that if the rate of increase of the window size is not excessive, this scheme is not harmful to the other connections that use a different version of TCP. Moreover, as expected, this scheme results in better performance for the connections with longer delays. However, choosing the parameters for such algorithms is still an open problem. Mo and Walrand [15] have demonstrated the existence of fair end-to-end window-based congestion control protocols and proposed an algorithm similar to TCP Vegas, for which convergence results are proved.

In this paper we explain the performance characteristics of TCP Vegas in relation to its queue-based control mechanisms; we demonstrate through both analysis and simulations that TCP Vegas does not suffer from delay bias as TCP Reno does. We

show the incompatibility of TCP Reno and TCP Vegas. The rest of the paper is organized as follows. In section 2 we describe the congestion detection and avoidance schemes of TCP Reno and TCP Vegas. Section 3 presents a few problems intrinsic in the original TCP Vegas and explains a possible solution to them. In section 4 we discuss the fairness of TCP Vegas using a simple closed fluid model. Section 5 compares TCP Vegas with TCP Reno and explains the incompatibility between them. We confirm our analysis with simulation results in section 6, and finish with some conclusions and future problems.

## II. CONGESTION AVOIDANCE MECHANISM

In order to make efficient use of network bandwidth, TCP controls its flow rate using the feedback from the network. In order to control its flow rate, TCP needs to estimate the available bandwidth in the network using a *bandwidth estimation scheme*. Among many new features implemented in TCP Vegas, the most important difference between TCP Vegas and TCP Reno lies in this bandwidth estimation scheme used to estimate the available bandwidth. As will be shown shortly, TCP Reno views packet losses as a signal of network congestion, while TCP Vegas uses the difference in the expected and actual rates to adjust its window size. This fundamental difference in the bandwidth estimation schemes enables TCP Vegas to utilize the available bandwidth more efficiently.

### A. TCP Reno

TCP Reno induces packet losses to estimate the available bandwidth in the network. While there are no packet losses, TCP Reno continues to increase its window size by one during each round trip time. When it experiences a packet loss, it reduces its window size to one half of the current window size. This is called *additive increase and multiplicative decrease*. The additive increase and multiplicative decrease algorithm is based on the results given in [3]. There it is shown that such an algorithm leads to a fair allocation of bandwidth. TCP Reno, however, fails to achieve such fairness because TCP is not a synchronized rate based control scheme, which is necessary for the convergence results of [3].

The congestion avoidance mechanism adopted by TCP Reno causes a periodic oscillation in the window size due to the constant update of the window size. This oscillation in the window size leads to an oscillation in the round trip delay of the packets. This oscillation results in larger delay jitter and an inefficient use of the available bandwidth due to many retransmissions of the same packets after packet drops occur.

## B. TCP Vegas

TCP Vegas adopts a more sophisticated bandwidth estimation scheme. It uses the difference between expected and actual flows rates to estimate the available bandwidth in the network. The idea is that when the network is not congested, the actual flow rate will be close to the expected flow rate. Otherwise, the actual flow rate will be smaller than the expected flow rate. TCP Vegas, using this difference in flow rates, estimates the congestion level in the network and updates the window size accordingly. Note that this difference in the flow rates can be easily translated into the difference between the window size and the number of acknowledged packets during the round trip time, using the equation

$$Diff = (Expected - Actual) BaseRTT, \quad (1)$$

where *Expected* is the expected rate, *Actual* is the actual rate, and *BaseRTT* is the minimum round trip time. The details of the algorithm are as follows:

1. First, the source computes the expected flow rate *Expected* =  $\frac{CWND}{BaseRTT}$ , where *CWND* is the current window size and *BaseRTT* is the minimum round trip time.
2. Second, the source estimates the current flow rate by using the actual round trip time according to *Actual* =  $\frac{CWND}{RTT}$ , where *RTT* is the actual round trip time of a packet.
3. The source, using the expected and actual flow rates, computes the estimated backlog in the queue from *Diff* =  $(Expected - Actual) BaseRTT$ .
4. Based on *Diff*, the source updates its window size as follows.

$$CWND = \begin{cases} CWND + 1 & \text{if } Diff < \alpha \\ CWND - 1 & \text{if } Diff > \beta \\ CWND & \text{otherwise} \end{cases}$$

Fig. 1. Window control of TCP Vegas

Figure 1 illustrates the behavior of TCP Vegas. Consider a simple network with one connection and one link with capacity  $C$ . Let *BaseRTT* be the minimum round trip delay. The throughput of this connection is  $\frac{window}{BaseRTT}$  when *window* <  $C \times BaseRTT$ . In the figure,  $w$  corresponds to the window size where *window* =  $C \times BaseRTT$ . When *window* >  $w$ , a queue starts to build up and  $(Expected - Actual) > 0$ . TCP Vegas increases the window size by one during the next round trip time if *window* <  $w + \alpha$  and decreases the window size by one if *window*

>  $w + \beta$ . Otherwise, it leaves the window size unchanged. In the figure, *Diff* is user  $i$ 's estimated backlogged queue size in the link. This will be explained in more details in section 3. TCP Vegas tries to keep at least  $\alpha$  packets but no more than  $\beta$  packets in the queues. The reason behind this is that TCP Vegas attempts to detect and utilize the extra bandwidth whenever it becomes available without congesting the network. Thus, when there is only one connection, the window size of TCP Vegas converges to a point that lies between  $w + \alpha$  and  $w + \beta$ . Note that this mechanism is fundamentally different from that used by TCP Reno. TCP Reno always updates its window size to guarantee full utilization of available bandwidth, leading to constant packet losses, whereas TCP Vegas does not cause any oscillation in window size once it converges to an equilibrium point.

## III. TCP VEGAS

TCP Vegas has a few problems that have not been discussed before, which could have a serious impact on its performance. One of the problems is the issue of rerouting. Since TCP Vegas uses an estimate of the propagation delay, *baseRTT*, to adjust its window size, it is very important for a TCP Vegas connection to have an accurate estimate of this quantity. Rerouting a path may change the propagation delay of the connection, and this could result in a substantial decrease in throughput. Another important issue is the stability of TCP Vegas. Since each TCP Vegas connection attempts to keep a few packets in the network, when the estimation of the propagation delay is off, this could lead the connections to inadvertently keep many more packets in the network, causing a persistent congestion. La *et al.*[13] have investigated these issues. We summarize the results here. For more details, refer to [13].

### A. Rerouting

TCP Vegas, as first suggested by Brakmo *et al.*[2], does not have any mechanism that handles the rerouting of connection. In this section, we show that such a lack of mechanisms could lead to strange behavior for TCP Vegas connections. Recall that in TCP Vegas *BaseRTT* is the smallest round trip delay, which is an estimate of the propagation delay of the path.

First, if the route of a connection is changed by a switch, then without an explicit signal from the switch, the end host cannot directly detect it. If the new route has a shorter propagation delay, this does not cause any serious problem for TCP Vegas because most likely some packets will experience shorter round trip delay and *BaseRTT* will be updated. On the other hand, if the new route for the connection has a longer propagation delay, the connection will not be able to tell whether the increase in the round trip delay is due to a congestion in the network or a change in the route. Without this knowledge the end host will interpret the increase in the round trip delay as a sign of congestion in the network and decrease the window size. This is, however, the opposite of what the source should do. When the propagation delay of connection  $i$  is  $d_i$ , the expected number of backlogged packets of the connection is  $w_i - r_i d_i$ , where  $w_i$  is connection  $i$ 's window size and  $r_i$  is the flow rate. Since TCP Vegas attempts to keep between  $\alpha$  and  $\beta$  packets in the switch buffers, if the propagation delay increases, then it should increase the window size to keep the same number of packets in the buffer. Because

TCP Vegas relies upon delay estimation, the rerouting could impact the performance substantially.

Since switches in the network do not notify the connections of changes in routes, it is required for sources of the connections to be able to detect such changes. La *et al.*[13] have suggested the following modification. For the first  $K$  packets, where  $K$  is a prefixed parameter, the modified protocol works the same way as TCP Vegas. After the ACK for the  $K$ th packet arrives, the source keeps track of the minimum round trip delay of  $N$  consecutive packets. If the minimum round trip time of the last  $L \cdot N$  packets is much larger than the current  $baseRTT$ , the source updates  $baseRTT$  to the minimum round trip time of the last  $N$  packets and resets the congestion window size based on this new  $baseRTT$ .

The basic idea behind this mechanism is as follows. If the minimum round trip time computed for  $N$  packets is consistently much higher than  $baseRTT$ , then it is likely that the actual propagation delay is larger than the measured  $baseRTT$ , and it makes sense to increase  $baseRTT$ . However, it is possible that the increase is due to a persistent congestion in the network. This problem is briefly discussed in section III-B. Since the increase in delay forces the source to decrease its window size, the round trip delay comes mostly from the propagation delay of the new route. Thus, the minimum round trip delay of the previous  $N$  packets is a good estimate of the new propagation delay, as is  $baseRTT$  for the previous route. The detailed description of the mechanism is given in [13] with simulation results.

### B. Persistent Congestion

Since TCP Vegas uses  $baseRTT$  as an estimate of the propagation delay of route, its performance is sensitive to the accuracy of  $baseRTT$ . Therefore, if the connections overestimate  $baseRTT$  due to a persistent congestion, the overestimation can have a substantial impact on the performance of TCP Vegas. We consider a scenario where the connections overestimate the propagation delays and possibly drive the system to a persistently congested state.

Suppose that a connection starts when there are many other existing connections, the network is congested, and the queues are backed up. Then, due to the queuing delay from other backlogged packets, the packets from the new connection may experience round trip delays that are considerably larger than the actual propagation delay of the path. Hence, the new connection will set the window size to a value such that it believes that its expected number of backlogged packets lies between  $\alpha$  and  $\beta$ , when in fact it has many more backlogged packets due to the inaccurate estimation of the propagation delay of the path. This scenario will repeat for each new connection, and it is possible that this causes the system to remain in a state of persistent congestion. This is exactly the opposite of what is desirable. When the network is congested, we do not want the new connections to make the congestion level worse. This same situation may arise with TCP Reno or TCP Tahoe. However, it is more likely to happen with TCP Vegas due to its fine-tuned congestion avoidance mechanism.

Once RED gateways are widely deployed, this problem can be handled by the same mechanism suggested in section III.A. The intuition behind this solution is as follows. When the network

stays in a persistently congested state, the connections interpret the lasting increase in the round trip delay as an increase in the propagation delay and update their  $baseRTT$ . This creates a temporary increase in congestion level in the network, and most connections, if not all, back off as they detect the congestion. As connections reduce their window sizes, the congestion level will come down, which allows the connections to estimate the correct  $baseRTT$ . Once most connections have an accurate measurement of the propagation delay, the congestion level will remain low. Since RED gateways drop packets independently, the synchronization effect will not be a big problem. For more details and simulation results, see [13].

## IV. FAIRNESS OF TCP VEGAS

As we have mentioned before, TCP Reno is biased against the connections with long delays [5], [7], [14]. In this section we show that TCP Vegas does not suffer from this delay bias as TCP Reno does by analyzing a simple closed fluid model, and confirm the resulting analysis by simulation in section 6. We assume that the packets are infinitely divisible, i.e., we use a fluid model, and the propagation delay is deterministic.

Fig. 2. Network with two users

Consider the simple network in Figure 2. There are two users with possibly different round trip delays, which share a single bottleneck link. User  $i$  has round trip delay  $d_i$  and exercises window-based flow control. Without loss of generality we assume that the capacity of the bottleneck link is normalized to one.

Let  $q_i(t)$  denote the user  $i$ 's queue size at time  $t$ ,  $q(t) = (q_1(t), q_2(t))$ , and  $z(t) = \sum_{i=1}^2 q_i(t)$ , which is the total backlog at time  $t$ . Define  $u_i(t) = z(t - u_i(t)) + d_i$ , which denotes the round trip delay experienced by user  $i$ 's packet whose ACK arrives at the source at time  $t$ . We assume that the switch adopts the *FIFO* service discipline and has infinite buffer size. Suppose  $e_i(t)$  denotes the rate at which connection  $i$  receives ACK, as shown in Figure 2, and the capacity is fully utilized, i.e.,  $e_1(t - d_1) + e_2(t - d_2) = 1$ . Users update their window sizes once during each round trip time.

Since the window size is equal to the sum of the amount of fluid in queue and in transit, at time  $t$  we have

$$w_i(t) = q_i(t) + \int_t^{t+d_i} e_i(s) ds. \quad (2)$$

Note that the second term on the right hand side is the amount of fluid in transit at time  $t$ . Each source computes the expected

backlog using the product of the propagation delay and the difference between the expected flow rate and the actual flow rate. Thus, the estimated amount of backlogged fluid computed by connection  $i$  is

$$Diff_i = w_i(t) - \frac{d_i}{u_i(t)} \int_{t-u_i(t)}^t e_i(s) ds. \quad (3)$$

A heuristic argument for the convergence of window sizes after some time  $t_0$  to a point such that

$$\alpha \leq w_i(t) - \frac{d_i}{u_i(t)} \int_{t-u_i(t)}^t e_i(s) ds \leq \beta \quad (4)$$

is given in the Appendix. Now suppose that window sizes satisfy equation (4). If we substitute (2) in (4), we have

$$\alpha \leq q_i(t) + \int_t^{t+d_i} e_i(s) ds - \frac{d_i}{u_i(t)} \int_{t-u_i(t)}^t e_i(s) ds \leq \beta. \quad (5)$$

Once the window sizes satisfy (4), the sources do not change the window size. Suppose that the system is quasi-static and  $e_i(t)$  is relatively constant. Then, the second and third terms in (5) cancel each other out, and it yields

$$\alpha \leq q_i(t) \leq \beta. \quad (6)$$

Note that under the quasi-static assumption the queue size and the estimated queue size in (3) of connection  $i$  do not depend on  $d_i$ . Since the server exercises the FIFO service discipline, the flow rate of each connection is proportional to its queue size. Therefore, the throughput of a connection does not depend on its propagation delay, and there is no bias in favor of connections with short delays. Furthermore, if  $\alpha$  and  $\beta$  are set to 1 and 3, respectively, the worst case ratio of throughput among the connections is at most 3.

If a connection with a larger delay wants to keep the same amount of fluid in the queue and similar throughput as a connection with a much shorter delay, it needs to have a bigger window size than the connection with a shorter delay because it needs more fluid in transit. This can be easily seen from (2). If both connections have same throughput, then the second term in (2) is directly proportional to the delay of the connection. Therefore, when all connections are receiving similar throughput, the window sizes of the connections should be roughly proportional to their propagation delays.

If we assume that the throughput and the queue size of each connection is relatively constant, then from (2) we get

$$w_i(t) = q_i(t) + e_i(t) \cdot d_i \quad (7)$$

and

$$e_i(t) = \frac{\text{window size}}{\text{round trip delay}} = \frac{w_i(t)}{z(t) + d_i}. \quad (8)$$

Since we have assumed that the capacity is fully utilized, from (8) we have

$$\frac{w_1(t)}{z(t) + d_1} + \frac{w_2(t)}{z(t) + d_2} = 1. \quad (9)$$

Hence, given the window sizes  $w_i(t)$ , we can compute  $z(t)$  by solving (9). By substituting the solution of (9) in (8) we

can compute the throughput of each connection. Plugging the solution of (8) in (7) yields the queue size of the connection. Thus, under the quasi-static assumption, we can compute the throughput and queue size of the connections, given the window sizes.

Fig. 3. Convergence Region

The simulation results show that the window sizes converge to a point such that the queue sizes computed from (7) - (9) are between  $\alpha$  and  $\beta$  for both connections. Figure 4 shows simulation results and Figure 3 describes how to read the plots in Figure 4. In Figure 3,  $\alpha_i$  and  $\beta_i$  lines for user  $i$  denote the sets of window size pairs  $\{(w_1, w_2) | w_i - e_i d_i = \alpha\}$  and  $\{(w_1, w_2) | w_i - e_i d_i = \beta\}$ , respectively, where  $e_i$  is connection  $i$ 's throughput computed from (7) - (9). The fairness line is the set of window size pairs such that the throughputs of the users are the same, i.e.,  $\{(w_1, w_2) | e_1 = e_2\}$ . In each plot of Figure 4 '+' denotes the converging point of TCP Vegas. As we can see, in each case it converges to a point  $(w_1, w_2)$  that satisfies

$$\alpha \leq q_i(w_1, w_2) \leq \beta, \quad i = 1, 2, \quad (10)$$

where  $q_i(w_1, w_2)$  is the queue size of connection  $i$  computed using (7) - (9). The numbers on the X-axis and Y-axis are the window sizes  $\times 10$ . The delay of connection 1 (Y-axis) is 12.9 ms in all plots and that of connection 2 (X-axis) is 18.9 ms, 36.9 ms, 66.9 ms, and 186.9 ms, respectively, from left to right and top to bottom.

Fig. 4. Converging point of TCP-Vegas with different delays.

## V. INCOMPATIBILITY OF TCP VEGAS WITH TCP RENO

There has been some previous work that demonstrates that in many cases TCP Vegas performs better than other implementations of TCP [2], [1]. However, Ahn *et al.* have observed that when a TCP Vegas user competes with other users that use TCP Reno, it does not receive a fair share of bandwidth due to the conservative congestion avoidance mechanism used by TCP Vegas.

TCP Reno continues to increase the window size until a packet is lost. Packet losses occur mainly due to buffer overflows. This bandwidth estimation mechanism results in a periodic oscillation of window size and buffer-filling behavior of TCP Reno. Thus, while TCP Vegas tries to maintain a smaller queue size, TCP Reno keeps many more packets in the buffer on the average, stealing higher bandwidth.

Let  $q_v(t)$  and  $q_r(t)$  denote the number of Vegas and Reno packets in the buffer at time  $t$ , and  $B$  be the buffer size. If we assume  $q_v(t) \approx k \leq \beta$ ,  $q_r(t)$  ranges from  $[0, B - k]$ . Assume that  $q_r(t)$  is distributed uniformly on the interval  $[0, B - k]$ . Then the average queue size of the Reno user  $\bar{q}_r(t)$  is approximately  $\frac{B-k}{2}$ . The ratio of TCP Vegas throughput to TCP Reno throughput is roughly  $\frac{2k}{B-k}$ . When  $B$  is relatively large, which is usually the case, then it is obvious that TCP Reno gets much higher bandwidth than TCP Vegas. We will confirm this analysis with simulation results in the next section.

The TCP Reno congestion avoidance scheme is aggressive in the sense that it leaves little room in the buffer for other connections, while TCP Vegas is conservative and tries to occupy little buffer space. When a TCP Vegas connection shares a link with a TCP Reno connection, the TCP Reno connection uses most of the buffer space and the TCP Vegas connection backs off, interpreting this as a sign of network congestion. This may be one of reasons why TCP Vegas is not widely deployed despite its many desirable properties. This same problem exists with the algorithm proposed by Mo and Walrand [15].

Although TCP Reno connections receive higher throughput than TCP Vegas connections when the buffer sizes are large, their packets experience unnecessarily long delays and jitter due to the large average queue sizes. TCP Vegas, on the other hand, maintains very small backlogs in the network, which results in short delays, and once the system reaches an equilibrium, the delay jitter becomes very small as well.

## VI. SIMULATION RESULTS

In order to verify the observations we have made through the heuristic analysis of simple networks, we have run simulations, using the network simulator (ns) developed at Lawrence Berkeley Laboratory [4]. We will discuss the simulation results in this section.

### A. Fairness of TCP Vegas

Figure 5 shows the topology of the network that was simulated to demonstrate the fairness of TCP Vegas. In the figure, the circles denote finite-buffer switches and the squares denote the end hosts. Connection 1 transmits packets from S1 to S3, and connection 2 from S2 to S4. The links are labeled with their capacities and propagation delays. The packet size is fixed at

Fig. 5. Network Topology

1,000 bytes. We vary the propagation delay of the link that connects R2 and S4, which is denoted by  $x$  in Figure 5, in order to see the effect of different delays on the throughputs.

$x$	$w_1$	$w_2$	$ACK_1$	$ACK_2$	$\frac{\max(ACK_1, ACK_2)}{\min(ACK_1, ACK_2)}$
4	3.5	3.5	21,425	16,068	1.33
13	4	7	17,522	19,965	1.14
22	4	7	20,061	17,427	1.15
58	4	13	19,507	17,973	1.09
148	4	30	21,068	16,398	1.29

TABLE I

TCP VEGAS WITH VARYING PROPAGATION DELAYS.

$x$	$ACK_1$	$ACK_2$	$ACK_1/ACK_2$
4	21,100	15,637	1.35
13	25,460	11,785	2.16
22	25,684	11,672	2.20
58	34,429	2,627	13.11
148	35,598	959	37.12

TABLE II

TCP RENO WITH VARYING PROPAGATION DELAYS.

Connections 1 and 2 start at time 0 and 0.5 seconds, respectively, and the simulation is run for 200 seconds. Tables I and II show the simulation results. In each table  $ACK_1$  and  $ACK_2$  are the number of packets that have been acknowledged by the corresponding receiver for connections 1 and 2. The last column shows the ratio of  $\max(ACK_1, ACK_2)$  to  $\min(ACK_1, ACK_2)$ .

Tables I and II clearly show that the delay bias of TCP Reno becomes very noticeable when the delay difference becomes large, while TCP Vegas does not show any such delay bias. The ratio of throughputs under TCP Vegas ranges from 1.09 to 1.33, whereas throughput ratio under TCP Reno increases almost linearly with delay ratio. This is consistent with our analysis given in previous sections and confirms that TCP Vegas does not suffer from the delay bias as TCP Reno does. We can also verify that the expected backlog for TCP Vegas connections at the converging point is between  $\alpha$  and  $\beta$  from (7) - (9).

### B. Incompatibility of Vegas with Reno

In the second part of simulation, we have simulated a network with two connections with same round trip delay of 24 ms, where one is a TCP Reno connection and the other is a TCP

Vegas connection, in an attempt to verify the incompatibility of TCP Vegas with TCP Reno. The packet size is again fixed at 1,000 bytes. We vary the buffer size at the switches to see how the relative performance of the TCP Vegas connection changes with the buffer size. The simulation results are given in Table III. The fourth column of the table is the ratio of throughputs, and the last column is the interval computed from  $\frac{B-k}{2k}$  as described in section 4, with  $k = 1$  and 3, since  $\alpha$  and  $\beta$  in TCP Vegas are usually set to 1 and 3, respectively, and  $k$  can be any number between  $\alpha$  and  $\beta$ .

Buffer	ACK(R)	ACK(V)	Reno/Vegas	Interval
4	13,010	24,308	0.535	[0.167, 1.5]
7	16,434	20,903	0.786	[0.667, 3.0]
10	22,091	15,365	1.438	[1.167, 4.5]
15	25,397	12,051	2.107	[2.0, 7.0]
25	30,798	6,621	4.652	[3.667, 12.0]
50	34,443	2,936	11.73	[7.833, 24.5]

TABLE III

THROUGHPUT OF VEGAS VS. RENO WITH DROP-TAIL GATEWAYS (R - RENO AND V - VEGAS). BUFFER SIZES ARE GIVEN IN PACKETS.

It is clear from Table III that TCP Vegas connection does not receive a fair share of bandwidth in the presence of a TCP Reno connection unless the buffer sizes are extremely small. Moreover, the ratios of the throughputs fall well within the region computed from the equation  $\frac{B-k}{2k}$ , suggested by our analysis.

### C. RED Gateways

The simulation results in the previous subsection suggest a way of making TCP Vegas more competitive in the presence of TCP Reno connections. Note in Table III that when the buffer sizes are small, TCP Vegas outperforms TCP Reno. The intuition behind this is as follows. TCP Reno needs some room in the switch buffer for oscillation in order to estimate the available bandwidth. Without the necessary room in the buffer, its performance degrades noticeably. TCP Vegas, on the other hand, quickly adapts to the small buffer size since it requires enough space for only a few packets.

This key observation tells us that Random Early Detection (RED) gateways could be used to make TCP Vegas more compatible with TCP Reno in a competitive environment [7]. RED gateways are characterized by a set of parameters, two of which are *threshold* and *maxthreshold*. RED gateways maintain an estimate of average queue size. When the average queue size exceeds *threshold* but is smaller than *maxthreshold*, they start dropping packets with certain probability that is proportional to the average queue size. If the average queue size exceeds *maxthreshold*, they drop all incoming packets. Hence, if the threshold values are set low enough, they give the connections an impression that the switch buffer size is smaller than it really is. This is discussed in more detail in [12].

The same network used in section VI.B is simulated again with RED gateways instead of drop-tail gateways. Each simulation is run for 100 seconds, and the buffer size is fixed at 25 packets. The buffer size, however, plays only a minor role if *maxthreshold* is

Threshold	Maxthreshold	ACK of Vegas	ACK of Reno
3	6	61,069	57,774
4	8	54,259	64,305
5	10	50,823	70,020
7	14	44,469	77,202
10	20	34,081	87,379

TABLE IV

THROUGHPUT OF VEGAS VS. RENO WITH RED GATEWAYS.

smaller than the buffer size. As summarized in Table IV, it is easy to see how the threshold values affect the relative performance of TCP Vegas against TCP Reno. As the threshold values increase, TCP Reno throughput increases at the cost of a decrease in TCP Vegas throughput. Also note that the total throughput increases slightly with the threshold values. This is obviously due to the decrease in the number of dropped packets.

## VII. CONCLUSIONS AND FURTHER PROBLEMS

In this paper we have analyzed the performance of TCP Vegas in comparison with TCP Reno. We have shown that TCP Vegas does lead to a fair allocation of bandwidth and explained some of its other characteristics. We have demonstrated through both analysis and simulations that TCP Vegas does not suffer from the delay bias as TCP Reno does. TCP Vegas achieves better performance than TCP Reno since its bandwidth estimation does not rely on packet losses in order to estimate the available bandwidth in the network. However, when competing with other TCP Reno connections, TCP Vegas gets penalized due to the aggressive nature of TCP Reno.

We are currently investigating the possibility of deploying TCP Vegas, adopting gateway control such as deficit round-robin (DRR) gateways. We first model the problem as a single shot game and explain the reason that TCP Vegas is difficult to deploy in the current Internet without providing a sufficient incentive. We suspect that we can provide the TCP Reno users with a proper incentive to switch to TCP Vegas by using DRR gateways to provide the necessary isolation among the users and thus inducing the users to cooperate with the network for their own benefit [11].

## APPENDIX

### I. CONVERGENCE OF WINDOW SIZES

In this appendix, we give a heuristic argument for the convergence of window sizes to a point  $(w_1, w_2)$  such that

$$\alpha \leq Diff_i = w_i(t) - \frac{d_i}{u_i(t)} \int_{t-u_i(t)}^t e_i(s) ds \leq \beta \quad (11)$$

During each round trip time source  $i$  computes the estimated backlog

$$Diff_i = w_i(t) - \frac{d_i}{u_i(t)} \int_{t-u_i(t)}^t e_i(s) ds, \quad (12)$$

and uses this estimate of the queue size to adjust its window size. We assume that  $e_i(t)$  and  $q_i(t)$  change slowly and remain steady, and the average converges. This is not an unreasonable assumption because TCP Vegas updates its window size at most by one during one round trip time. Therefore,  $e_i(t)$  and  $q_i(t)$  do not change too fast. Now suppose that the sources use the average throughput to adjust their window sizes. For the simplicity of notation, we omit the dependency on time  $t$ . We have the following equations from (12) and the assumption.

$$Diff_i = w_{i,avg} - e_{i,avg} \cdot d_i \quad (13)$$

$$e_{i,avg} \approx \frac{w_{i,avg}}{z_{avg} + d_i} \quad (14)$$

If we assume that the capacity is fully utilized, we get

$$1 = e_{1,avg} + e_{2,avg} \approx \frac{w_{1,avg}}{z_{avg} + d_1} + \frac{w_{2,avg}}{z_{avg} + d_2}. \quad (15)$$

Hence, given the window sizes  $w_{i,avg}$  we can compute an approximate value for  $z_{avg}$  from (15). The solution of (15) can be used to compute  $e_{i,avg}$  and  $Diff_i$  from (13) and (14). The sources update their window size based on  $Diff_i$ .

Figure 6 illustrates the convergence region of TCP Vegas. In the figure,  $\alpha_i$  and  $\beta_i$  lines for user  $i$  denote the sets of window size pairs  $\{(w_1, w_2) | Diff_i = \alpha\}$  and  $\{(w_1, w_2) | Diff_i = \beta\}$ , respectively, from equations (13) - (15). The fairness line is the set of window size pairs such that the throughputs of the users are

Fig. 6. Convergence region of TCP Vegas

the same, i.e.,  $\{(w_1, w_2) | e_1 = e_2\}$ . User 1 increases its window size in regions (1), (4), and (7), and decreases its window size in regions (3), (6), and (9). Similarly, user 2 increases its window size in regions (7), (8), and (9), and decreases its window size in regions (1), (2), and (3).

Figure 6 is a typical plot of convergence region for two users, and the same geometric picture can be easily extended to a case with more than two users. The only region in the figure where neither user updates its window size is region (5). The arrows in other regions indicate the directions in which the window sizes may get updated.

We will show in Theorem 1 that the window sizes converges to a point in region (5) within a finite amount of time, assuming that the distance between  $\alpha_i$  and  $\beta_i$  lines is sufficiently large compared to  $\delta > 0$ , the amount by which users update their window sizes. Suppose  $(w_1, w_2) = (w_1(0), w_2(0))$ . Let

$$A = \{(w_1 + \delta n_1, w_2 + \delta n_2) \mid 0 \leq w_1 + \delta n_1 \leq w_{1,max}, 0 \leq w_2 + \delta n_2 \leq w_{2,max}, n_1, n_2 \in \mathcal{Z}\},$$

where  $w_{1,max}$  and  $w_{2,max}$  are the maximum congestion window sizes declared by the receivers. Then,  $A$  is the set of all possible window size pairs. If  $w_{1,max}$  and  $w_{2,max}$  are finite, then  $N = |A|$  is finite. We will first state a lemma that will be used in the proof of Theorem 1. Suppose that the distance between the  $\alpha_i$  and  $\beta_i$  lines is at least  $\sqrt{2}\delta$ .

**Lemma 1:** No window size pair outside region (5) can be visited twice.

**Proof:** Suppose that there exists a window size pair that could be visited twice outside region (5). Then, this implies that there exists a loop generated by window size updates as shown in Figure 7. We will now show that no such loop can exist.

In regions (1) through (6), user 2 never increases its window size. Hence, if user 2 updates in regions (1) through (3), then it is not possible to return to the same windows size pair since we have assumed that the distance between  $\alpha_2$  line and  $\beta_2$  line is larger than  $\delta$ . Moreover, if user 1 updates its window size in either region (1) or (3), then the previous window size pair cannot be revisited without reaching either region (2) or (5) because user 1 does not update its window size in the opposite direction in the same region. However, once the window sizes reach a point in region (2) or (5), then for the same reason given above, it is not possible to return to the previous window size pair because

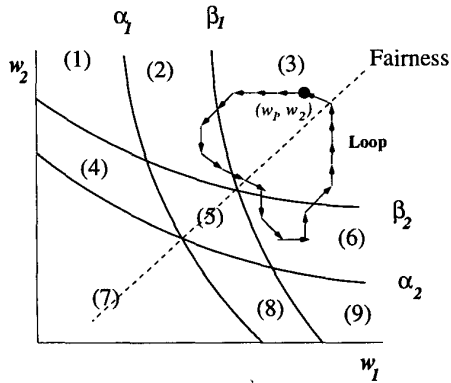

Fig. 7. An example of a loop

at most only user 2 will update its window size and decrease it. Therefore, it is not possible for a window size pair in region (1) through (3) to be visited more than once. By symmetry between users 1 and 2, it is not possible to have such a loop for a window size pair in region (3), (6), and (9).

Similarly, since user 2 does not decrease its window size in region (4) through (9), none of window size pairs in regions (7) through (9) can be visited twice. Again by symmetry, the same is true for regions (1), (4), and (7). Therefore, none of the window size pairs outside region (5) can be visited more than once. ■

*Theorem 1:* The window sizes converge to a point in region (5) within a finite amount of time, starting from a point in the region bounded by  $w_{1,max}$  and  $w_{2,max}$ .

*Proof:* From Lemma 1 we know that no window size pair outside region (5) can be visited more than once. Therefore, if  $(w_1, w_2) = (w_1(0), w_2(0))$  and  $N = |A|$ , then assuming that the time between window size updates of each connection is finite, the window sizes converge to a point in (5) because there are at most  $N-1$  other pairs the window size pair could take on before it reaches a point in region (5), and once the window sizes are in region (5), they do not change. ■
